## Orbital Branching

January 20, 2009

#### Abstract

We introduce orbital branching, an effective branching method for integer programs containing a great deal of symmetry. The method is based on computing groups of variables that are equivalent with respect to the symmetry remaining in the problem after branching, including symmetry which is not present at the root node. These groups of equivalent variables, called orbits, are used to create a valid partitioning of the feasible region which significantly reduces the effects of symmetry while still allowing a flexible branching rule. We also show how to exploit the symmetries present in the problem to fix variables throughout the branch-and-bound tree. Orbital branching can easily be incorporated into standard integer programming software. Through an empirical study on a test suite of symmetric integer programs, the question as to the most effective orbit on which to base the branching decision is investigated. The resulting method is shown to be quite competitive with a similar method known as isomorphism pruning and significantly better than a state-of-the-art commercial solver on symmetric integer programs.

Key words. Integer programming - symmetry - branch-and-bound algorithms

## 1. Introduction

In this work, we focus on packing and covering integer programs (IP)s of the form

$$
\begin{gather*}
\max _{x \in\{0,1\}^{n}}\left\{e^{T} x \mid A x \leq e\right\} \text { and }  \tag{PIP}\\
\min _{x \in\{0,1\}^{n}}\left\{e^{T} x \mid A x \geq e\right\}, \tag{CIP}
\end{gather*}
$$

where $A \in\{0,1\}^{m \times n}$, and $e$ is a vector of ones of conformal size. Our particular focus is on cases when (CIP) or (PIP) is highly-symmetric, a concept we formalize as follows. Let $\Pi^{n}$ be the set of all permutations of $I^{n}=\{1, \ldots, n\}$. Given a permutation $\pi \in \Pi^{n}$ and a permutation $\sigma \in \Pi^{m}$, let $A(\sigma, \pi)$ be the matrix obtained by permuting the rows of $A$ by $\sigma$ and the columns of $A$ by $\pi$, i.e. $A(\sigma, \pi)=P_{\sigma} A P_{\pi}$, where $P_{\sigma}$ and $P_{\pi}$ are the permutation matrices corresponding to $\sigma$ and $\pi$ respectively. The symmetry group $\mathcal{G}$ of the matrix $A$ is the set of permutations

$$
\mathcal{G}(A) \stackrel{\text { def }}{=}\left\{\pi \in \Pi^{n} \mid \exists \sigma \in \Pi^{m} \text { such that } A(\sigma, \pi)=A\right\}
$$

[^0]So, for any $\pi \in \mathcal{G}(A)$, if $\hat{x}$ is feasible for (CIP) or (PIP) (or the LP relaxations of (CIP) or (PIP)), then if the permutation $\pi$ is applied to the coordinates of $\hat{x}$, the resulting solution, which we denote as $\pi(\hat{x})$, is also feasible. Moreover, the solutions $\hat{x}$ and $\pi(\hat{x})$ have equal objective value.

This equivalence of solutions induced by symmetry is a major factor that might confound the branch-and-bound process. For example, suppose $\hat{x}$ is a (non-integral) solution to an LP relaxation of PIP or CIP, with $0<\hat{x}_{j}<1$, and the decision is made to branch down on variable $x_{j}$ by fixing $x_{j}=0$. If $\exists \pi \in \mathcal{G}(A)$ such that $[\pi(\hat{x})]_{j}=0$, then $\pi(\hat{x})$ is a feasible solution for this child node, and $e^{T} \hat{x}=e^{T}(\pi(\hat{x}))$, so the relaxation value for the child node will not change. If the cardinality of $\mathcal{G}(A)$ is large, then there are many permutations through which the parent solution of the relaxation can be preserved in this manner, resulting in many branches that do not change the bound on the parent node. Furthermore, symmetric solutions appear again and again all over the tree. Symmetry has long been recognized as a curse for solving integer programs, and auxiliary (often extended) formulations are often sought that reduce the amount of symmetry in an IP formulation [2,9,19]. In addition, there is a body of research on valid inequalities that can help exclude symmetric feasible solutions [14,26]. Kaibel and Pfetsch [11] formalize many of these arguments by defining and studying the properties of a polyhedron known as an orbitope, the convex hull of lexicographically maximal solutions with respect to a symmetry group. Kaibel et al. [10] then use the properties of orbitopes to remove symmetry in partitioning problems.

A different idea, isomorphism pruning, introduced by Margot [15,16] in the context of IP, examines the symmetry group of the problem in order to prune isomorphic subproblems of the enumeration tree. The branching method introduced in this work, orbital branching, also uses the symmetry group of the problem. However, instead of examining this group to ensure that only one node in the equivalence class of the group will be evaluated, the group is used to guide the branching decision. At the cost of potentially evaluating isomorphic subproblems, orbital branching allows for considerably more flexibility in the choice of branching entity than isomorphism pruning. Furthermore, orbital branching can be easily incorporated within a standard integer programming solver and even exploit problem symmetry that may only be locally present at a nodal subproblem.

A preliminary version of this work has been published in the conference proceedings of the the Twelfth Conference on Integer Programming and Combinatorial Optimization (IPCO) [22]. The remainder of the paper is divided into six sections. In Section 2 we give some mathematical preliminaries. Orbital branching is introduced and formalized in Section 3. Enhancements to orbital branching are discussed in Section 4, and a more complete comparison to isomorphism pruning is also presented there. Implementation details are provided in Section 5, and computational results are presented in Section 6. Conclusions about the impact of orbital branching and future research directions are given in Section 7.

## 2. Preliminaries

Orbital branching is based on elementary concepts from algebra that we recall in this section to make the presentation self-contained. Some definitions are made in terms of an arbitrary permutation group $\Gamma$, but for concreteness, the reader may consider the group $\Gamma$ to be the symmetry group of the matrix $\mathcal{G}(A)$.

For a set $S \subseteq I^{n}$, the orbit of $S$ under the action of $\Gamma$ is the set of all subsets of $I^{n}$ to which $S$ can be sent by permutations in $\Gamma$, i.e.,

$$
\operatorname{orb}(S, \Gamma) \stackrel{\text { def }}{=}\left\{S^{\prime} \subseteq I^{n} \mid \exists \pi \in \Gamma \text { such that } S^{\prime}=\pi(S)\right\}
$$

In orbital branching we are concerned with the orbits of sets of cardinality one, corresponding to decision variables $x_{j}$ in PIP or CIP. By definition, if $j \in \operatorname{orb}(\{k\}, \Gamma)$, then $k \in \operatorname{orb}(\{j\}, \Gamma)$, i.e. the variable $x_{j}$ and $x_{k}$ share the same orbit. Therefore, the union of the orbits

$$
\mathcal{O}(\Gamma) \stackrel{\text { def }}{=} \bigcup_{j=1}^{n} \operatorname{orb}(\{j\}, \Gamma)
$$

forms a partition of $I^{n}=\{1,2, \ldots, n\}$, which we refer to as the orbital partition of $\Gamma$, or simply the orbits of $\Gamma$. The orbits encode which variables are "equivalent" with respect to the symmetry $\Gamma$.

The stabilizer of a set $S \subseteq I^{n}$ in $\Gamma$ is the set of permutations in $\Gamma$ that send $S$ to itself.

$$
\operatorname{stab}(S, \Gamma)=\{\pi \in \Gamma \mid \pi(S)=S\} .
$$

The stabilizer of $S$ is a subgroup of $\Gamma$.
Throughout this paper, we display permutations in cyclic notation. The expression $\left(p_{1}, p_{2}, \ldots, p_{k}\right)$ denotes a cycle which sends entry $p_{i}$ to $p_{i+1}$ for $i=1, \ldots, k-1$ and sends $p_{k}$ to $p_{1}$. Permutations may be written as a product of cycles. We will omit all 1 -element cycles from our display. For more detailed information on groups, the reader is invited to refer to [3, 7,24].

We characterize a node $a=\left(F_{1}^{a}, F_{0}^{a}\right)$ of the branch-and-bound enumeration tree by the indices of variables fixed to one $F_{1}^{a}$ and fixed to zero $F_{0}^{a}$ at node $a$. The set of free variables at node $a$ is denoted by $N^{a}=I^{n} \backslash F_{0}^{a} \backslash F_{1}^{a}$. At node $a$, the set of feasible solutions to (CIP) or (PIP) is denoted by $\mathcal{F}(a)$, and the value of an optimal solution for the subtree rooted at node $a$ is denoted as $z^{*}(a)$.

## 3. Orbital Branching

In this section we introduce orbital branching, an intuitive way to exploit the orbits of the symmetry group $\mathcal{G}(A)$ when making branching decisions. The classical 0-1 branching variable dichotomy does not take advantage of the problem information encoded in the symmetry group. To take advantage of this information in orbital branching, instead
of branching on individual variables, orbits of variables are used to create the branching dichotomy. Informally, suppose that at the current subproblem there is an orbit of cardinality $k$ in the orbital partitioning. In orbital branching, the current subproblem is split into $k+1$ subproblems: the first $k$ subproblems are obtained by fixing to one in turn each variable in the orbit while the $(k+1)^{\mathrm{st}}$ subproblem is obtained by fixing all variables in the orbit to zero. For any pair of variables $x_{i}$ and $x_{j}$ in the same orbit, the subproblem created when $x_{i}$ is fixed to one is essentially equivalent to the subproblem created when $x_{j}$ is fixed to one. Therefore, we can keep in the subproblem list only one representative subproblem, pruning the $(k-1)$ equivalent subproblems. This is formalized below.

### 3.1. Orbital Branching: Description

Let $A\left(F_{1}^{a}, F_{0}^{a}\right)$ be the matrix obtained by removing from the constraint matrix $A$ all columns in $F_{0}^{a} \cup F_{1}^{a}$ and either all rows intersecting columns in $F_{1}^{a}$ (CIP case) or all columns nonorthogonal to columns in $F_{1}^{a}$ (PIP case). When we remove columns from the matrix, we do not change the index on any of the remaining columns. Keeping the original indices introduces some notational difficulties that can be overcome by introducing a suitable mapping. Precisely, permutations $\pi$ acting on the set of free variables $N^{a}$ can be extended to act on $I^{n}$ by creating a permutation in $I^{n}$ which acts identically to $\pi$ in the set $N^{a}$ while not moving any fixed elements corresponding to fixed variables. This mapping, $\phi:[0,1]^{n} \rightarrow[0,1]^{\left|N^{a}\right|}$ with $\phi(x)_{i}=x_{i}$ for all $i \in N^{a}$, also maps feasible solutions with respect to $A$ to feasible solutions with respect to $A\left(F_{1}^{a}, F_{0}^{a}\right)$. Therefore, for simplicity of exposition, we will think of all permutations as acting on the set $I^{n}$ and we will not differentiate solutions which are feasible at node $a$ with solutions feasible with respect to $A\left(F_{1}^{a}, F_{0}^{a}\right)$.

Let $O=\left\{i_{1}, i_{2}, \ldots, i_{|O|}\right\} \subseteq N^{a}$ be an orbit of the symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$. Given a subproblem $a$, the disjunction

$$
\begin{equation*}
x_{i_{1}}=1 \vee x_{i_{2}}=1 \vee \ldots x_{i_{O}}=1 \vee \sum_{i \in O} x_{i}=0 \tag{1}
\end{equation*}
$$

splits the search space. In what follows, we show that for any two variables $x_{j}, x_{k} \in O$, the two children $a(j)$ and $a(k)$ of $a$, obtained by fixing respectively $x_{j}$ and $x_{k}$ to 1 have the same optimal solution value. As a consequence, disjunction (1) can be replaced by the binary disjunction

$$
\begin{equation*}
x_{h}=1 \vee \sum_{i \in O} x_{i}=0, \tag{2}
\end{equation*}
$$

where $h$ is a variable in $O$. Formally, we have Theorem 1.
Theorem 1. Let $O$ be an orbit in the orbital partitioning $\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)\right)$, and let $j, k$ be two variable indices in $O$. If $a(j)=\left(F_{1}^{a} \cup\{j\}, F_{0}^{a}\right)$ and $a(k)=\left(F_{1}^{a} \cup\{k\}, F_{0}^{a}\right)$ are the child nodes created when branching on variables $x_{j}$ and $x_{k}$, then $z^{*}(a(j))=$ $z^{*}(a(k))$.

Proof. Let $x^{*}$ be an optimal solution of $a(j)$ with value $z^{*}(a(j))$. Obviously $x^{*}$ is also feasible for $a$. Since $j$ and $k$ are in the same orbit $O$, there exists a permutation $\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ such that $\pi(j)=k$. By definition, $\pi\left(x^{*}\right)$ is a feasible solution of $a$ with value $z^{*}(a(j))$ such that $x_{k}=1$. Therefore, $\pi\left(x^{*}\right)$ is feasible for $a(k)$, and $z^{*}(a(k))=z^{*}(a(j))$.

In fact, the proof of Theorem 1 establishes a slightly stronger result. Namely, if there exists a solution of value $T$ in $a(j)$, then there exists a (symmetric) solution of value $K$ in $a(k)$. The basic orbital branching method is formalized in Algorithm 1.

```
Algorithm 1 Orbital Branching
    Input: \(\quad\) Subproblem \(a=\left(F_{1}^{a}, F_{0}^{a}\right)\), non-integral solution \(\hat{x}\).
    Output: Two child subproblems \(b\) and \(c\).
    Step 1. Compute orbital partition \(\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)\right)=\left\{O_{1}, O_{2}, \ldots, O_{p}\right\}\).
    Step 2. Select orbit \(O_{j^{*}}, j^{*} \in\{1,2, \ldots, p\}\).
    Step 3. Choose arbitrary \(k \in O_{j^{*}}\). Return subproblems \(b=\left(F_{1}^{a} \cup\{k\}, F_{0}^{a}\right)\) and \(c=\left(F_{1}^{a}, F_{0}^{a} \cup O_{j^{*}}\right)\).
```

The consequence of Theorem 1 is that the search space is limited, but orbital branching has also the relevant effect of reducing the likelihood of encountering symmetric solutions. Namely, no solutions in the left and right child nodes of the current node will be symmetric with respect to the local symmetry. This is formalized in Theorem 2.

Theorem 2. Let $b$ and $c$ be any two subproblems in the enumeration tree. Let a be the first common ancestor of $b$ and $c$. If $a \neq b, a \neq c$, then there $\exists x \in \mathcal{F}(b)$ such that $\exists \pi \in \mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ with $\pi(x) \in \mathcal{F}(c)$.

Proof. Suppose not, i.e., that there $\exists x \in \mathcal{F}(b)$ and a permutation $\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ such that $\pi(x) \in \mathcal{F}(c)$. Let $O_{i} \in \mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)\right)$ be the orbit chosen to branch on at subproblem $a$. W.l.o.g. we can assume $x_{k}=1$ for some $k \in O_{i}$, that is, $b$ is in the left branch of $a$. We have that $x_{k}=[\pi(x)]_{\pi(k)}=1$, but $\pi(k) \in O_{i}$. Therefore, by the orbital branching dichotomy, $\pi(k) \in F_{0}^{c}$, so $\pi(x) \notin \mathcal{F}(c)$.
Note that by using the matrix $A\left(F_{1}^{a}, F_{0}^{a}\right)$, orbital branching attempts to use symmetry found at all nodes in the enumeration tree, not just the symmetry found at the root node. This makes it possible to prune nodes whose corresponding solutions are not symmetric in the original IP.

### 3.2. Orbital Branching: An Illustrative Example

Example 1. In order to demonstrate the effects of orbital branching, consider the graph $G=(V, E)$ of Figure 1 and the associated PIP:

$$
\begin{aligned}
\max \sum_{i \in V} x_{i} & \\
x_{i}+x_{j} & \leq 1 \quad \forall\{i, j\} \in E, \\
x_{i} & \in\{0,1\} \quad \forall i \in V
\end{aligned}
$$

Fig. 1. Example
which corresponds to computing the stability number of $G$.
Applying Step 1 of Algorithm 1 at the root subproblem $F_{1}^{a}=F_{0}^{a}=\emptyset$ results in a group $\mathcal{G}(A)$ containing 4096 permutations and an orbital partition $\mathcal{O}(\mathcal{G}(A))$ containing two orbits, namely, $O_{1}=\{1, \ldots, 8\}$ and $O_{2}=\{9, \ldots, 24\}$. Thanks to the structure of the matrix $A$, in which each constraint corresponds to an edge of $G$, the orbits of $\mathcal{G}(A)$ can be intuitively visualized on the graph.

Step 2 of Algorithm 1 selects an orbit on which to base the branching dichotomy. Suppose the largest orbit $O_{2}$ is chosen, and the branching index $k=9 \in O_{2}$ is used. Then, two subproblems $b$ and $c$ are generated as follows: $F_{1}^{b}=\{9\}$ and $F_{0}^{b}=\emptyset$; $F_{1}^{c}=\emptyset$ and $F_{0}^{c}=\{9, \ldots, 24\}$. The structure of subproblems $b$ and $c$, where fixed variables have been removed, is drawn in Figure 2.

The advantage of orbital branching over classical branching on a variable is highlighted by completely executing two branch-and-bound algorithms on the PIP of Example 1 . We assume that a feasible solution of (optimal) value 8 is found at the root node. In the first algorithm the branching decision is carried out by orbital branching where Step 2 selects the largest orbit. In the second algorithm, ordinary branching is performed on the variable corresponding to the vertex of $G$ with maximum degree in the remaining graph, typically effective for stable set problems [25]. In Figures 3 and 4, the complete enumeration trees obtained respectively by orbital branching and branching on variable are drawn. At each node $a$, we report the variables fixed $\left(F_{1}^{a}, F_{0}^{a}\right)$ and the value of the LP relaxation $z_{L P}$. Orbital branching results in fewer evaluated subproblems: 21 vs .49 for the variable-branching dichotomy.

An insightful explanation of orbital branching's improved performance is obtained by examining the structure of subproblems. For instance, Figure 5 shows the graphs

subproblem $b$

subproblem $c$

Fig. 2. Child subproblems
remaining at subproblems 9 and 19 of the variable-branching enumeration tree. The graphs are isomorphic, but both subproblems are evaluated when branching on variables. On the contrary, orbital branching breaks such a symmetry at the root subproblem. The complete catalog of graphs and orbital partitions for each subproblem in the orbital branching branch-and-bound tree is reported in the Appendix. Looking at the catalog of subproblems, one can observe that no isomorphic subproblems are evaluated when orbital branching is used on this example. This is not, however, true in general.

## 4. Enhancements to Orbital Branching

In this section, we demonstrate how additional variables may be fixed during branch and bound by considering the implications of symmetry. We also discuss how to perform orbital branching by considering a subgroup of the original symmetry group. We compare orbital branching to a related technique for combating symmetry in integer programs, isomorphism pruning. The section concludes with a brief discussion on how to most effectively employ orbital branching on integer programs whose optimal solution has a large support.

### 4.1. Orbital Fixing

In orbital branching, all variables fixed to zero and one are removed from the constraint matrix at every node in the enumeration tree. As Theorem 2 demonstrates, using orbital branching in this way ensures that any two nodes are not equivalent with respect to the symmetry found at their first common ancestor. It is possible however, for two child subproblems to be equivalent with respect to a symmetry group found elsewhere in the tree. In order to combat this type of symmetry we perform orbital fixing, which works as follows.

$$
\begin{array}{lll}
z_{\text {LP }}=10.5
\end{array}
$$

Fig. 3. Enumeration tree with orbital branching

Fig. 4. Enumeration tree with branching on variable

subproblem 9

subproblem 19

Fig. 5. isomorphic subproblems from branching on variable

Consider the symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ at node $a$. If there exists an orbit $O$ in the orbital partition $\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)$ that contains variables such that $O \cap F_{0}^{a} \neq \emptyset$ and $O \cap N^{a} \neq \emptyset$, then all variables in $O$ can be fixed to zero. In the following theorem, we show that such variable setting (orbital fixing) excludes feasible solutions only if there exists a feasible solution of the same objective value to the left of the current node in the branch and bound tree. (We assume that the enumeration tree is oriented so that the branch with an additional variable fixed at one is the left branch).

To aid in our development, we introduce the concept of a focus node. For $x \in \mathcal{F}(a)$, we call node $b(a, x)$ a focus node of $a$ with respect to $x$ if $\exists y \in \mathcal{F}(b)$ such that $e^{T} x=$ $e^{T} y$ and $b$ is found to the left of $a$ in the tree.

Theorem 3. Let $\left\{O_{1}, O_{2}, \ldots O_{q}\right\}$ be an orbital partitioning of $\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ at node $a$, and let the set

$$
S \stackrel{\text { def }}{=}\left\{j \in N^{a} \mid \exists k \in F_{0}^{a} \text { and } j, k \in O_{\ell} \text { for some } \ell \in\{1,2, \ldots q\}\right\}
$$

be the set of free variables that share an orbit with a variable fixed to zero at a. If $x \in \mathcal{F}(a)$ with $x_{i}=1$ for some $i \in S$, then either there exists a focus node for a with respect to $x$ or $x$ is not an optimal solution.

Proof. Let $S \neq \emptyset$. Then, there exist $j \in F_{0}^{a}$ and $i \in S$ such that $i \in \operatorname{orb}\left(j, \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)$, i.e., there exists a $\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ with $\pi(i)=j$. W.l.o.g., suppose that $j$ is any of the first such variables fixed to zero on the path from the root node to $a$ and let $c$ be the first subproblem in which $j$ is fixed. Let $\rho(c)$ be the parent node of $c$. By our choice of $j$ as the first fixed variable, $\left\{\pi(i) \mid \forall i\right.$ s.t. $x_{i}=1$ and $\left.\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right\} \cap F_{0}^{\rho(c)}=\emptyset$. Therefore, $\pi(x)$ is not feasible in $a$ since it does not satisfy the bounds, but is feasible in $\rho(c)$ and has the same objective value of $x$.

The variable $x_{j}$ could have been fixed either $(i)$ as a result of a branching decision, or (ii) it was deduced that no optimal solution exists with $x_{j}=1$ at node $\rho(c)$ (and the fixing applied to the child nodes), or (iii) by orbital fixing (at $\rho$ ).

- (i) If $j$ was fixed by orbital branching then the left child of $\rho(c)$ has $x_{h}=1$ for some $h \in \operatorname{orb}\left(j, \mathcal{G}\left(A\left(F_{1}^{\rho(c)}, F_{0}^{\rho(c)}\right)\right)\right)$. Let $\pi^{\prime} \in \mathcal{G}\left(A\left(F_{1}^{\rho(c)}, F_{0}^{\rho(c)}\right)\right)$ have $\pi^{\prime}(j)=h$. Then $\pi^{\prime}(\pi(x))$ is feasible in the left node with the same objective value of $x$. The left child node of $\rho(c)$ is then the focus node of $a$ with respect to $x$.
- (ii) If it was deduced that no optimal solution feasible at $\rho(c)$ exists with $x_{j}=1$, then, since $\pi(x)$ is feasible in $\rho(c)$ with $x_{j}=1$, and $\pi$ preserves objective value, $x$ cannot be an optimal solution.
- (iii) Lastly, $j$ could have been fixed by orbital fixing. This implies that the set $S$ is nonempty in $\rho(c)$ and the argument can be repeated until the first ancestor $d$ of $a$ is reached such that $F_{0}^{d}$ does not contain variables fixed by orbital fixing. Therefore, a sequence of permutations $\pi^{1}, \ldots, \pi^{r}$ has been found such that $\pi^{r} \pi^{r-1} \ldots \pi^{1} \pi(x)$ is feasible in $d$ and has the same value of $x$.
Then, either argument $(i)$ or $(i i)$ can be applied, that is, either there is a focus node $f$ of $d$ with respect to $\pi^{r} \pi^{r-1} \ldots \pi^{1} \pi(x)$ (which would also be a focus node for $a$ with respect to $x$ ), or $j$ was fixed by an optimality condition (which implies $\pi^{r} \pi^{r-1} \ldots \pi^{1} \pi(x)$ and thus $x$ are not optimal).

There may be elements in $S$ which do not share an orbit with $j$. One can show that these elements can also be fixed by adding the fixed variables to $F_{0}$, updating $S$, and repeating the argument. As long as $S$ is non-empty, each iteration will fix at least one variable.

An immediate consequence of Theorem 3 is that for all $i \in F_{0}^{a}$ and for all $j \in$ $\operatorname{orb}\left(i, \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)$ one can set $x_{j}=0$. We update orbital branching to include orbital fixing in Algorithm 2.

```
Algorithm 2 Orbital Branching with Orbital Fixing
    Input: \(\quad\) Subproblem \(a=\left(F_{1}^{a}, F_{0}^{a}\right)\) (with free variables \(\left.N^{a}=I^{n} \backslash F_{1}^{a} \backslash F_{0}^{a}\right)\), fractional solution
        \(\hat{x}\).
    Output: \(\quad\) Two child nodes \(b\) and \(c\).
    Step 1. Compute orbital partition \(\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)=\left\{\hat{O}_{1}, \hat{O}_{2}, \ldots, \hat{O}_{q}\right\}\). Let \(S \stackrel{\text { def }}{=}\{j \in\)
        \(N^{a} \mid \exists k \in F_{0}^{a}\) and \((j \cap k) \in \hat{O}_{\ell}\) for some \(\left.\ell \in\{1,2, \ldots q\}\right\}\).
    Step 2. Compute orbital partition \(\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)\right)=\left\{O_{1}, O_{2}, \ldots, O_{p}\right\}\).
    Step 3. Select orbit \(O_{j^{*}}, j^{*} \in\{1,2, \ldots, p\}\).
    Step 4. Choose arbitrary \(k \in O_{j^{*}}\). Return child subproblems \(b=\left(F_{1}^{a} \cup\{k\}, F_{0}^{a} \cup S\right)\) and \(c=\)
        \(\left(F_{1}^{a}, F_{0}^{a} \cup O_{j^{*}} \cup S\right)\).
```

In orbital fixing, the set $S$ of additional variables set to zero depends on $F_{0}^{a}$. Variables may appear in $F_{0}^{a}$ due to a branching decision or due to traditional methods for variable fixing in integer programming, e.g. reduced cost fixing or implication-based fixing. Orbital fixing, then, gives a way to enhance traditional variable-fixing methods by including the symmetry present at a node of the branch and bound tree.

Example (continued) When orbital branching with orbital fixing is applied to the PIP of Example 1, it generates the enumeration tree drawn in Figure 6. Orbital fixing is performed at subproblem 6 , a node that has $F_{0}^{6}=\{11,12,23,24\}$ and $F_{1}^{6}=$

Fig. 6. Enumeration tree with orbital branching and orbital fixing
$\{9,15\}$. The group $\mathcal{G}\left(A\left(F_{1}^{6}, \emptyset\right)\right)$ yields the orbits: $\{2,3\}\{5,8\}\{6,7\}\{11,12,13,14\}$ $\{17,18,23,24\}\{19,20,21,22\}$. The orbit $\{11,12,13,14\}$ contains variables that have already been set to zero: $\{11,12,13,14\} \cap F_{0}^{a}=\{13,14\}$. Therefore, the variables $x_{13}$ and $x_{14}$ are fixed to 0 by orbital fixing. In the same way, looking at the orbit $\{17,18,23,24\}$, orbital fixing sets variables $x_{17}$ and $x_{18}$ to 0 . All the variables fixed to 0 by orbital fixing are underlined in Figure 6.

The effect of orbital fixing is clear at subproblem 6, where the optimal value of the LP relaxation reduces from 9 to 7, as compared to the algorithm without orbital fixing, avoiding further branching (see the tree of Figure 3).

The example also helps illustrate the existence of a focus node if orbital fixing is performed (Theorem 3). Define $a$ as the subproblem found at node 6 . The set of variables fixed by orbital fixing is $S=\{13,14,17,18\}$. Consider the solution $x \in \mathcal{F}(a): x_{2}=$ $x_{5}=x_{8}=x_{9}=x_{13}=x_{15}=x_{19}=x_{21}=1$, and all other variables set to 0 . Following the proof of Theorem 3, we have $i=13$ and $j \in \operatorname{orb}\left(\{i\}, \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)$, i.e., $j=$ 12. A permutation $\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ such that $\pi(i)=j$ is: $[(2,3),(12,13),(11,14)]$. We have $\bar{x}=\pi(x)$, that is, $\bar{x}_{2}=\bar{x}_{5}=\bar{x}_{8}=\bar{x}_{12}=\bar{x}_{19}=\bar{x}_{21}=1$, and all other variables set to 0 . Notice that $\bar{x} \notin \mathcal{F}(a)$, since $x_{12}=1$. By definition, subproblem 5 is the subproblem $c$ in the proof of Theorem 3, and subproblem 2 is the subproblem $\rho(c)$. Then, we have $h=11$ and $\pi^{\prime}$ can be defined as: $(11,12)$. Finally, $\tilde{x}=\pi^{\prime}(\pi(x))$ is: $\bar{x}_{3}=\bar{x}_{7}=\bar{x}_{9}=\bar{x}_{11}=\bar{x}_{15}=\bar{x}_{17}=\bar{x}_{19}=\bar{x}_{23}=1$, and all other variables set to 0 . This is feasible for subproblem 4 . Thus, 4 is a focus node for $a$.

### 4.2. Using a Subgroup of the Original Symmetry Group

We delay discussion of the computation of the symmetry groups $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ until Section 5.1, but we simply note at this point that all known algorithms which compute the symmetry group of a given graph have exponential running time. Thus, computing the symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ at each node $a$ may be computationally prohibitive. We will show via computational results in Section 6 that this is often not the case. In the case that recomputing the full symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ is too costly, there is an alternative. Instead, orbital branching can use the symmetry group $\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ to create orbits at every node in the tree. In this method, the original, global, symmetry group $\mathcal{G}(A)$ is only computed once, at the root node, and the stabilizers are computed given the original symmetry group. This is typically more computationally efficient than re-computing the symmetry groups from scratch. In the following, in order to distinguish between the two symmetry groups that could be used in orbital branching at node $a$, we will refer to $\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ as the global symmetry group (because we use only the symmetry group found at the root node), and $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ as the local symmetry group.

The decreased computational overhead in orbit calculations when using the global symmetry group comes at a price. As Theorems 4 and 5 demonstrate, the orbits from the global group $\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ are a subdivision of the orbits used for orbital fixing and orbital branching, so the branching dichotomy and fixing mechanisms are weaker.

Theorem 4. If $O \in \mathcal{O}\left(\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)\right)$ and $O \cap F_{1}^{a}=\emptyset$, then $\exists O^{\prime} \in \mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right)$ with $O \subseteq O^{\prime}$.

Proof. We prove Theorem 4 by proving the following equivalent statement: if $\exists \pi \in$ $\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ with $\pi(i)=j$ and $i, j \notin F_{1}^{a}$, then $\exists \pi^{\prime} \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ with $\pi(i)=j$. Let $\pi \in \operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ be such that $\pi(i)=j$ and $i, j \notin F_{1}^{a}$. Since $\pi\left(F_{1}^{a}\right)=F_{1}^{a}$ we can restrict $\pi$ by ignoring its action on $F_{1}^{a}$. Let $C^{a}$ be the collection of inequalities which have been removed (become redundant) either at $a$ or any parent of $a$. Since $\pi \in \operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$, there exists a $\sigma \in \Pi^{m}$ such that $A(\sigma, \pi)=A$. Each constraint, $c^{T} x \geq(\leq) 1$, in $C^{a}$ contains at least one variable in $F_{1}^{a}$. This constraint gets mapped to $\sigma(c)^{T} \pi(x) \geq(\leq) 1$, a constraint still containing at least one variable in $F_{1}^{a}$, hence a constraint in $C^{a}$. We can then restrict $\sigma$ by ignoring its action on the constraint set $C^{a}$. Call the pair of restricted permutations $\pi^{\prime}$ and $\sigma^{\prime}$. These permutations act on the same set of variables and constraints as $\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$. We also have that $A\left(F_{1}^{a}, \emptyset\right)\left(\pi^{\prime}, \sigma^{\prime}\right)=$ $A\left(F_{1}^{a}, \emptyset\right)$, so $\pi^{\prime} \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ with $\pi(i)=j$.

Orbital fixing does not change the result of Theorem 4. Specifically, if $S^{a}$ is the set of indices of variables fixed to zero by orbital fixing at node $a$, then the orbits from the group $\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ are a subdivision of orbits from the group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a} \cup S^{a}\right)\right)$.

Theorem 5. Let $S^{a}$ be the set of variables fixed to zero by orbital fixing at node a. If $O \in \mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)\right), \exists O^{\prime} \in \mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a} \cup S^{a}\right)\right)\right)$ with $O \subseteq O^{\prime}$.

Proof. We prove Theorem 5 by proving the equivalent statement that if $\exists \pi \in$ $\mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ with $\pi(i)=j$ and $i, j \notin S^{a}$, then $\exists \pi^{\prime} \in \mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a} \cup S^{a}\right)\right)$ with $\pi(i)=j$. Let $\pi \in \mathcal{G}\left(A\left(F_{1}^{a}, \emptyset\right)\right)$ with $\pi(i)=j$. We can restrict $\pi$ by ignoring its actions on the set $F_{0}^{a} \cup S^{a}$. Call the restricted permutation $\pi^{\prime}$. Let $C^{a}$ be the collection of inequalities which have been removed (become redundant) either at $a$ or any parent of $a$. We know that there exists a $\sigma \in \Pi^{m-\left|C^{a}\right|}$ such that $A\left(F_{1}^{a}, \emptyset\right)(\pi, \sigma)=A\left(F_{1}^{a}, \emptyset\right)$. Since $A\left(F_{1}^{a}, F_{0}^{a}\right)$ contains the same rows as $A\left(F_{1}^{a}, \emptyset\right)$, we have that $A\left(F_{1}^{a}, F_{0}^{a}\right)\left(\pi^{\prime}, \sigma\right)=$ $A\left(F_{1}^{a}, F_{0}^{a}\right)$.

### 4.3. Comparison to Isomorphism Pruning

The fundamental idea behind isomorphism pruning is that for each node $a=\left(F_{1}^{a}, F_{0}^{a}\right)$, the orbits $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ of the "equivalent" sets of variables to $F_{1}^{a}$ are computed. If there is a node $b=\left(F_{1}^{b}, F_{0}^{b}\right)$ elsewhere in the enumeration tree such that $F_{1}^{b} \in$ $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right)$, then the node $a$ need not be evaluated-the node $a$ is pruned by isomorphism. A very distinct and powerful advantage of this method is that no nodes whose sets of variables fixed to 1 are isomorphic will be evaluated. One disadvantage of this method is that computing $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ can require significant computational effort. Further the set $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ may contain many equivalent subsets to $F_{1}^{a}$, and the entire enumeration tree must be compared against this list to ensure that $a$ is not isomorphic to any other node $b$. In a series of papers, Margot offers a way around this second disadvantage $[15,16]$. The key idea introduced is to declare one unique representative among the members of $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right)$, and if $F_{1}^{a}$ is not the unique representative, then the node $a$ may safely be pruned. The oracle that checks if $F_{1}^{a}$ a unique
representative among $\operatorname{orb}\left(F_{1}^{a}, \mathcal{G}(A)\right.$ runs in polynomial time. The disadvantage of the method is ensuring that the unique representative occurs somewhere in the branch and bound tree requires a relatively inflexible branching rule. Namely, all child nodes at a fixed depth must be created by branching on the same variable.

Orbital branching does not suffer from this inflexibility. By not focusing on pruning all isomorphic nodes, but rather eliminating the symmetry through branching, orbital branching offers a great deal more flexibility in the choice of branching entity. Another advantage of orbital branching is that by using the symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$, symmetry introduced as a result of the branching process is also exploited.

Both methods allow for the use of traditional integer programming methodologies such as cutting planes and fixing variables based on considerations such as reduced costs and implications derived from preprocessing. In isomorphism pruning, for a variable fixing to be valid, it must be that all non-isomorphic optimal solutions are in agreement with the fixing. Orbital branching does not suffer from this limitation. A powerful idea in both methods is to combine the variable fixing with symmetry considerations in order to fix many additional variables. This idea is called orbit setting in [16] and orbital fixing in this work (see Sec. 4.1).

### 4.4. Reversing Orbital Branching

One of the advantages of orbital branching is that the "right" branch, in which all variables in the branching orbit $O$ are fixed to zero, typically changes the optimal value of the LP relaxation significantly, and the left branch, in which one variable in $O$ is fixed to one also has a significant impact on the problem. In some classes of PIP or CIP, fixing a variable to zero can have more impact than fixing a variable to one. This is typically true in instances in which the number of ones in an optimal solution is larger than $1 / 2$ the number of variables. In such cases, orbital branching would be much more efficient if all variables were complemented, or equivalently if the orbital branching dichotomy (2) was replaced by its complement. Margot [16] also makes a similar observation for the isomorphism pruning algorithm and solves the complemented versions of such instances. In orbital branching, we opt for the former way of exploiting this fact, and the "left" branch fixes one variable to zero, and orbital fixing fixes variables to one instead of zero.

## 5. Implementation

The orbital branching method has been implemented using the user application functions of MINTO v3.1 [21]. The branching dichotomy of Algorithm 1 or 2 is implemented in the appl_divide () method, and reduced cost fixing is implemented in appl_bounds (). The entire implementation, including code for all the branching rules subsequently introduced in Section 5.2 consists of slightly over 1000 lines of code. All advanced IP features of MINTO were used, including clique inequalities, which can be useful for instances of (PIP). In this section, we discuss the features of the implementation that are specific to orbital branching-the computation of the symmetry groups and orbital branching rules.

### 5.1. Computing $\mathcal{G}(\cdot)$

Computation of the symmetry groups required for orbital branching and orbital fixing is done by computing the automorphism group of a related graph. Recall that the automorphism group $\operatorname{Aut}(G(V, E))$ of a graph $G=(V, E)$, is the set of permutations of $V$ that leave the incidence matrix of $G$ unchanged, i.e.

$$
\operatorname{Aut}(G(V, E))=\left\{\pi \in \Pi^{|V|} \mid\{i, j\} \in E \Leftrightarrow\{\pi(i), \pi(j)\} \in E\right\}
$$

The matrix $A$ whose symmetry group is to be computed is transformed into a bipartite graph $G(A)=(N, M, E)$ where vertex set $N=\{1,2, \ldots, n\}$ represents the variables, vertex set $M=\{n+1, n+2, \ldots, n+m\}$ represents the constraints, and edge $(i, j) \in E$ if and only if $a_{i j}=1$. Under this construction, feasible solutions to (PIP) are subsets of the vertices $S \subseteq N$ such that each vertex $i \in M$ is adjacent to at most one vertex $j \in S$. In this case, we say that $S$ packs $M$. Feasible solutions to (CIP) correspond to subsets of vertices $S \subseteq N$ such that each vertex $i \in M$ is adjacent to at least one vertex $j \in S$, or $S$ covers $M$. Since applying members of the automorphism group preserves the incidence structure of a graph, if $S$ packs (covers) $M$, and $\pi \in \operatorname{stab}(M, \operatorname{Aut}(G(A)))$, then there exists a $\sigma \in \Pi^{M}$ such that $\sigma(M)=M$ and $\pi(S)$ packs (covers) $\sigma(M)$. This implies that if $\pi \in \operatorname{stab}(M, \operatorname{Aut}(G(A)))$, then the restriction of $\pi$ to $N$ must be an element of $\mathcal{G}(A)$, i.e. using the graph $G(A)$, one can find elements of symmetry group $\mathcal{G}(A)$. In particular, we compute the orbital partition of the stabilizer of the constraint vertices $M$ in the automorphism group of $G(A)$, i.e.

$$
\mathcal{O}(\operatorname{stab}(M, \operatorname{Aut}(G(A))))=\left\{O_{1}, O_{2}, \ldots, O_{p}\right\}
$$

The orbits $O_{1}, O_{2}, \ldots, O_{p}$ in the orbital partition are such that if $i \in M$ and $j \in N$, then $i$ and $j$ are not in the same orbit. We can then refer to these orbits as variable orbits and constraint orbits. In orbital branching, we are concerned only with the variable orbits.

There are several software packages that can compute the automorphism groups required to perform orbital branching. The program nauty [18], by McKay, has been shown to be quite effective [5], and we use nauty in our orbital branching implementation.

The complexity of computing the automorphism group of a graph is not known to be polynomial time. However, nauty was able to compute the symmetry groups of our problems very quickly, generally faster than solving an LP at a given node. One explanation for this phenomenon is that the running time of nauty's backtracking algorithm is correlated to the size of the symmetry group being computed. For example, computing the automorphism group of the clique on 2000 nodes takes 85 seconds, while graphs of comparable size with little or no symmetry require fractions of a second. The orbital branching procedure quickly reduces the symmetry group of the child subproblems, so explicitly recomputing the group by calling nauty is computational very feasible. In the table of results presented in the Appendix, we state explicitly the time required in computing automorphism groups by nauty.

### 5.2. Branching Rules

The orbital branching rule introduced in Section 3 leaves significant freedom in choosing the orbit on which to base the branching (Step 2 of Algorithm 1). In this section, we discuss mechanisms for deciding on which orbit to branch. As input to the branching decision, we are given a fractional solution $\hat{x}$ and orbits $O_{1}, O_{2}, \ldots O_{p}$ (consisting of all currently free variables) of the orbital partition $\mathcal{O}\left(\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)\right)$ for the subproblem at node $a$. Output of the branching decision is an index $j^{*}$ of an orbit on which to base the orbital branching. We tested six different branching rules.
Rule 1: Branch Largest: The first rule chooses to branch on the largest orbit $O_{j^{*}}$ :

$$
j^{*} \in \arg \max _{j \in\{1, \ldots, p\}}\left|O_{j}\right| .
$$

Rule 2: Branch Largest LP Solution: The second rule branches on the orbit $O_{j^{*}}$ whose variables have the largest total solution value in the fractional solution $\hat{x}$ :

$$
j^{*} \in \arg \max _{j \in\{1, \ldots, p\}} \hat{x}\left(O_{j}\right) .
$$

Rule 3: Strong Branching: The third rule is a strong branching rule. For each orbit $j$, two tentative child nodes are created and their bounds $z_{j}^{+}$and $z_{j}^{-}$are computed by solving the resulting linear programs. The orbit $j^{*}$ for which the product of the change in linear program bounds is largest is used for branching:

$$
\begin{equation*}
j^{*} \in \arg \max _{j \in\{1, \ldots, p\}}\left(\left|e^{T} \hat{x}-z_{j}^{+}\right|\right)\left(\left|e^{T} \hat{x}-z_{j}^{-}\right|\right) . \tag{3}
\end{equation*}
$$

We also tested using a combination of the bound changes
$j^{*} \in \arg \max _{j \in\{1, \ldots, p\}}\left(3 \min \left(\left|e^{T} \hat{x}-z_{j}^{+}\right|,\left|e^{T} \hat{x}-z_{j}^{-}\right|\right)+\max \left(\left|e^{T} \hat{x}-z_{j}^{+}\right|,\left|e^{T} \hat{x}-z_{j}^{-}\right|\right)\right)$, as suggested by [12], but the computational results using equation (3) were slightly stronger.

Note that if one of the potential child nodes in the strong branching procedure would be pruned, either by bound or by infeasibility, then the bounds on the variables may be fixed to their values on the alternate child node. We refer to this as strong branching fixing, and in the computational results in the Appendix, we report the number of variables fixed in this manner. As discussed at the end of Section 4.1, variables fixed by strong branching fixing may result in additional variables being fixed by orbital fixing.

Rule 4: Break Symmetry Left: This rule is similar to strong branching, but instead of fixing a variable and computing the change in objective value bounds, we fix a variable and compute the change in the size of the symmetry group. Specifically, for each orbit $j$, we compute the size of the symmetry group in the resulting left branch if orbit $j$ (including variable index $i_{j}$ ) was chosen for branching, and we branch on the orbit that reduces the symmetry by as much as possible:

$$
j^{*} \in \arg \min _{j \in\{1, \ldots, p\}}\left(\left|\mathcal{G}\left(A\left(F_{1}^{a} \cup\left\{i_{j}\right\}, F_{0}^{a}\right)\right)\right|\right)
$$

| Name | Variables | Group Size |
| :---: | ---: | ---: |
| cod83 | 256 | $10,321,920$ |
| cod93 | 512 | $185,794,560$ |
| $\operatorname{cod} 105$ | 1024 | $3,715,891,200$ |

| sts63 | 63 | 72,576 |
| sts81 | 81 | $1,965,150,720$ |

Table 1. Symmetric Integer Programs

Rule 5: Keep Symmetry Left: This branching rule is the same as Rule 4, except that we branch on the orbit for which the size of the child's symmetry group would remain the largest:

$$
j^{*} \in \arg \max _{j \in\{1, \ldots, p\}}\left(\left|\mathcal{G}\left(A\left(F_{1}^{a} \cup\left\{i_{j}\right\}, F_{0}^{a}\right)\right)\right|\right)
$$

Rule 6: Branch Max Product Left: This rule attempts to combine the fact that we would like to branch on a large orbit at the current level and also keep a large orbit at the second level on which to base the branching dichotomy. For each orbit $O_{1}, O_{2}, \ldots, O_{p}$, the orbits $P_{1}^{j}, P_{2}^{j}, \ldots, P_{q}^{j}$ of the symmetry group $\mathcal{G}\left(A\left(F_{1}^{a} \cup\left\{i_{j}\right\}, F_{0}^{a}\right)\right)$ of the left child node are computed for some variable index $i_{j} \in O_{j}$. We then choose to branch on the orbit $j^{*}$ for which the product of the orbit size and the largest orbit of the child subproblem is largest:

$$
j^{*} \in \arg \max _{j \in\{1, \ldots p\}}\left(\left|O_{j}\right|\left(\max _{k \in\{1, \ldots q\}}\left|P_{k}^{j}\right|\right)\right) .
$$

## 6. Computational Experiments

In this section, we give empirical evidence of the effectiveness of orbital branching, we investigate the impact of choosing the orbit on which branching is based, and we demonstrate the positive effect of orbital fixing. The computations are based on the instances whose characteristics are given in Table 1. The instances beginning with cod are used to compute maximum cardinality binary error correcting codes [13], the instances whose names begin with cov are covering designs [20], the instance $f 5$ is the "football pool problem" on five matches [8], and the instances sts are used to compute the incidence width of the well-known Steiner-triple systems [6]. The cov formulations have been strengthened with a number of Schöenheim inequalities, as derived by Margot [17]. The sts instances typically have roughly $2 / 3$ of the variables equal to one in an optimal solution, so for these instances, we reverse the orbital branching dichotomy, as explained in Section 4.4. All instances, save for $£ 5$, are available from Margot’s web site: http://wpweb2.tepper.cmu.edu/fmargot/lpsym.html.

The computations comparing different orbital branching rules were run on machines with AMD Opteron processors clocked at 1.8 GHz and having 2GB of RAM. The COIN-OR software Clp was used to solve the linear programs at nodes of the branch and bound tree. For each instance, the (known) optimal solution value was set $a$ priori to aid pruning and reduce the random impact of finding a feasible solution in the search. Nodes were searched in a depth-first fashion. When the size of the maximum orbit in the orbital partitioning is less than or equal to two, nearly all of the symmetry in the problem has been eliminated by the branching procedure, and there is little use in performing orbital branching. In this case, we use MINTO's default branching strategy [12]. If orbital branching is not performed at a node, then there is little likelihood that it will be effective at the node's children. In this case, we save the computational overhead of re-computing the symmetry group, and simply allow MINTO to choose a branching variable. The CPU time was limited in all cases to four hours, and a limit of one million nodes evaluated was imposed.

Table 2 shows the results of an experiment designed to compare the performance of the six different orbital branching rules introduced in Section 5.2. In this experiment, reduced cost fixing, orbital fixing, and the local symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ were used, and the CPU time required (in seconds) and number of nodes required for orbital branching to solve each instance in the test suite for the six different is reported. A "-" in the table indicates that the instance was not solved within the four hour or one million node limit. A complete table showing the number of nodes, CPU time, CPU time computing automorphism groups, the number of variables fixed by reduced cost fixing, orbital fixing, and strong branching fixing, and the deepest tree level at which orbital branching was performed for a variety of parameter settings is shown in Table 5 in the Appendix.

In order to succinctly present many of our computational results, we use performance profiles of Dolan and Moré [4]. A performance profile is a relative measure of the effectiveness of one solution method in relation to a group of solution methods on a fixed set of problem instances. A performance profile for a solution method $m$ is essentially a plot of the probability that the performance of $m$ (measured in this case with CPU time or number of nodes evaluated) on a given instance in the test suite is within a factor of $\beta$ of the best method for that instance. Methods whose corresponding profile lines are the highest are the most effective. Figure 7 shows a performance profile of the results of the first experiment, using CPU times from Table 2 as a measure of performance, and Figure 8 shows the performance profile using the number of nodes as a measure of performance.

In terms of CPU time, the most effective branching method is Rule 5-the method that keeps the size of the symmetry group large on the left branch. (This method gives the "highest" line in Fig. 7). In fact, this branching method is the only one that is able to solve all of the instances in the test suite within the four hour time limit. This result is somewhat surprising. Anecdotally, symmetry has long been thought to be a significant hurdle for solving integer programs. One might expect that methods in which symmetry was removed as quickly as possible would have been the most effective. Our results go counter to this intuition. Instead, if effective methods for exploiting problem symmetry (like those in orbital branching) are present, the results indicate that one should attempt to keep a large amount of symmetry in the subproblems.

| Instance | Rule 1 | Rule 2 | Rule 3 | Rule 4 | Rule 5 | Rule 6Time Nodes |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table 2. CPU Time and Nodes for Orbital Branching Using Local Symmetry Group

Fig. 7. CPU Time Performance Profile of Branching Rules

Another interesting result in this computational experiment is that the number of nodes required to solve the instance is nearly always the smallest using Rule 3-strong branching. (Note the height of the strong branch line in Figure 8). In fact, if strong branching can solve the problem instance within the time limit, then it requires the fewest number of nodes. However, since many linear programs are solved to determine the best branching orbit, strong branching quite often is the slowest of the branching methods in terms of CPU time. We view the performance of strong branching as a positive demonstration of the fact that exploiting the flexibility offered by orbital branching (as opposed to the more static branching rules offered by isomorphism pruning) may for some instances have a positive impact on running time. More sophisticated orbital branching implementations may choose to implement advanced "hybrid" branching

Fig. 8. Nodes Evaluated Performance Profile of Branching Rules
rules that perform limited strong branching, like the reliability branching of Achterberg, Koch, and Martin [1].

A second experiment was aimed at measuring the impact of using the the global symmetry group $\operatorname{stab}\left(F_{1}^{a}, \mathcal{G}(A)\right)$ (discussed in Section 4.2) instead of the local symmetry group $\mathcal{G}\left(A\left(F_{1}^{a}, F_{0}^{a}\right)\right)$ when making a branching decision. Table 3 shows the CPU time (in seconds) orbital branching, equipped with reduced cost fixing and orbital fixing, required on the instances in the test suite, for the different branching rules employing the global symmetry group.

Table 3. CPU Time and Nodes for Orbital Branching Using Global Symmetry Group

Again, branching Rule 5 that keeps symmetry on the left child node, was the most effective. A side-by-side comparison of Tables 2 and 3 indicates that in general using the
global symmetry group is more effective than attempting to exploit symmetry that may only be locally present at a node. Figure 9 shows a performance profile comparing the CPU time required to solve the instances using branching Rule 5 with both the local and global symmetry groups. Surprisingly, the improved performance of the global symmetry group comes not only from improved efficiency of the branching calculations, but in many cases the number of nodes is reduced, which can be seen by comparing the relevant columns in Tables 2 and 3. These computational results run counter to Theorem 4, which states that orbits from the global symmetry group are a subdivision of orbits from the local group. Since the orbits of the local group are no smaller, one would expect that orbital branching's enumeration tree would also be smaller in this case.

Fig. 9. Performance Profile of Local versus Global Symmetry Groups

A third comparison worthy of note is the impact of performing orbital fixing, as introduced in Section 4.1. Using branching Rule 5, each instance in Table 1 was run both with and without orbital fixing. Figure 10 shows a performance profile comparing the results in the two cases. The results shows that orbital fixing has a significant positive impact.

The final comparison we make in the paper is between different branch and bound techniques for solving the symmetric test instances. Five different algorithms were compared: the isomorphism pruning algorithm of Margot, orbital branching (using branching Rule 5 and the global symmetry group), MINTO's default algorithm, CPLEX v11.2 without symmetry handling, and CPLEX v11.2 with symmetry handling. The symmetry handling was changed in CPLEX by setting the option symmetry to 0 or 5 respectively. As orbital branching is implemented in the MINTO framework, the MINTO default results demonstrate the direct impact of orbital branching on the symmetric test instances. In this experiment, we dropped the one million node limit, and imposed only

Fig. 10. Performance Profile of Impact of Orbital Fixing
a CPU time limit of four hours. Table 4 summarizes the results of the comparison. The results for isomorphism pruning are taken directly from the paper of Margot using the most sophisticated of his branching rules "BC4" [16] running on a HP-B2000 workstation with a 500 MHz CPU. The paper [16] does not report results on $f 5$. The CPLEX results were obtained on an Intel Core 2 Duo P8600 clocked at 2.40 Ghz , as this is the machine on which a CPLEX license was available. Since the results were obtained on three different computer architectures and each used a different LP solver for the child subproblems, the CPU times should be interpreted appropriately. Regardless of the impact of the CPU on performance, the results clearly show that isomorphism pruning and orbital branching are the most effective methods for these symmetric instances.

Table 4. Comparison of Different Solvers on Test Instances

## 7. Conclusions

In this work, we presented a simple way to capture and exploit the symmetry of an integer program when branching. We showed through a set of experiments that the new method, orbital branching, outperforms CPLEX, a state-of-the-art solver, when a high degree of symmetry is present. Orbital branching also seems to be of comparable quality to the isomorphism pruning method of Margot [16]. Further, we feel that the simplicity and flexibility of orbital branching make it an attractive candidate for further study. Continuing research includes techniques for further reducing the number of isomorphic nodes that are evaluated, for implementing the natural extension of the orbital branching method on more general classes of integer programs, on developing branching mechanisms that combine the child bound improvement and change in symmetry in a meaningful way, and on exploiting symmetry when branching on constraints instead of variables [23].

## Acknowledgments

The authors would like to thank Kurt Anstreicher and François Margot for inspiring and insightful comments on this work. In particular, the name orbital branching was suggested by Kurt. The comments of two anonymous referees and the associate editor helped improve the paper considerably. Author Linderoth would like to acknowledge support from the US National Science Foundation (NSF) under grant DMI-0522796, by the US Department of Energy under grant DE-FG02-05ER25694, and by IBM, through the faculty partnership program. Author Ostrowski is supported by the NSF through the IGERT Grant DGE-9972780.

Table 6. Performance of Orbital Branching Rules (Global Symmetry) on Symmetric IPs

Fig. 11. Example 1: Structure of Subproblems and Orbits in Orbital Branching.
1

$\{1,2,3,4,5,6,7,8\}$
$\{9,10,11,12,13,14,15,16,17$,
$18,19,20,21,22,23,24\}$

2

$\{2,8\}\{3,7\}\{4,6\}\{5\}$
$\{11,12,23,24\}\{13,14,21,22\}$
$\{15,16,19,20\}\{17,18\}$

$\{3,8\}\{4,7\}\{5,6\}$
$\{13,14,23,24\}$
$\{15,16,21,22\}\{17,18,19,20\}$

3

$\{1,2,3,4,5,6,7,8\}$

5

$\{2,8\}\{3,7\}\{4,6\}\{5\}$
$\{13,14,21,22\}\{15,16,19,20\}$
$\{17,18\}$
